ABSTRACT

Introduction: Stature is considered as one of the important parameters for personal identification. So, Stature reconstruction is important as it provides forensic anthropological estimation of the height of a person in the living state which plays a vital role in the identification of individual remains.

Aim: The aim of the present study was to investigate the association of hand length with height and to show if height could be predicted using hand length measurements in students of SKIMS Medical college.

Methodology: The study of the anthropometric characteristics of 100 Medical College students of ages between 18-23 years of SKIMS Medical college, Bemina with no obvious deformities or previous history of trauma to the spine or hand was undertaken. The study of these medical students, males (n=50) & females (n=50) was investigated. The anthropometric characteristics of their height and hand length were measured, analysed statistically for any significant difference, and correlation between the parameters studied.

Results: The results show some significant differences between the anthropometric parameters, Pearson's correlation analysis was used and showed a strong positive correlation, which means that high X variable scores go with high Y variable scores. (R is 0.8229) and it is significant. Results from the present study show that there was a positive correlation between height and hand length indicating that height could be predicted using hand length.

Conclusion: As age groups increase the mean length of hand also increase, so there is direct relation between length of hand and age groups. Definite proportion also exists between the height and hand length in an individual at all ages, irrespective of the sex. Height of an individual is 9 times the height of hand length. Thus we can predict height from hand length when it is difficult or not possible to measure height directly.

KEY WORDS: Height, Hand Length, Anthropometry, Medical College.
undergone amputations [4,5]. For example in scoliosis patients, the predicted spirometric values were underestimated when the measured body was used and under such circumstances, an estimate of height has to be computed based on another body parameters [6,7].

The height achieved by the individuals is under the control of genes and environment. As the growth is measured by measuring the height of a person, which itself is a sum of the length of certain bones and appendages of the body. This relationship is very useful anthropologically to find racial differences and medico-legally, when only parts of the deceased body are available [8].

Ascertaining sex and estimation of stature from incomplete skeletal and decomposing bodies is a recurring theme in physical anthropology and forensic science [9-12] as stature is considered as one of the important parameters for personal identification [13,14]. The hand length was found to be the most reliable alternative that can be used as a basis for estimating age-related loss in height. The length of the body while alive is one of the key parameters established in the course of identification of unknown skeletal remains [15,16]. Amirsheybani et al (2000) found that hand length can be a good predictor of the body surface area independent of the sex of the individual [2].

The most important applications of anthropology at field level include biological anthropology, epidemiology, clinical application and in metabolic research [17,18]. The hand length could be used to predict body weight status and body surface area independent of the sex of the individual [18]. Thus a reliable and precise means in predicting the height of an individual is by knowing the hand length of the individual [19,20].

The dimensions of the hand and foot have been used in the determination of sex, age, stature of an individual by forensic experts in forensic examinations. Stature reconstruction is important as it provides forensic anthropological estimation of the height of a person in the living state which plays a vital role in the identification of individual remains [21,22]. Intact long limb bones have been used in the derivation of regression equations for stature assessment in different population groups. Anthropologist observes and compared the relation between body and segments to highlight variations between and within groups. The major concern in forensic medicine and forensic anthropology is determination of a stature [23].

The bone area values at different sites strongly correlates to muscle strength and also correlate to body size; height, weight, lean mass, fat mass and body mass index (BMI) [23]. It is commonly accepted that standards for skeletal identification vary among different populations and the standard for one population may not be used for another [24,25].

Establishing personal identification of the victims is often required and the estimation of stature from extremities and their parts plays an important role in identifying the dead in forensic examinations (26). The reconstruction of body stature has been a subject of study since the beginning of the nineteenth century in the specialized areas of forensic anthropology which deals with the application of methods and techniques of analysing skeletal remains [27,25,28].

The aim of the present study was to investigate the association of hand length with height and to show if height could be predicted using hand length measurements in students of SKIMS Medical college.

MATERIALS AND METHODS

This study was carried out among first year students of SKIMS Medical college in Kashmir, India. The sample consists of 100 (males = 50, females = 50) with no known physical deformities between the ages of 17-23 years. The inclusion criteria include that participants must be a first year medical student between the ages of 17-23 years without any known physical or mental deformity. The demographic data of the subjects collected include the age in years, name, place of birth, parental and grandparental origin were completed in the questionnaire. Standing height and hand length measurements were done.

Standing height was measured to the nearest metres (cms) using a Stadiometer with subject...
standing erect on a horizontal resting plane bare
footed having the palms of the hands turned
inward and the finger pointing downwards and
the height was then converted to the nearest
meters (cms). The height was measured from
the sole of the feet to the vertex of the head as
recommended by International Biological
Program [29,30].

The measurements were taken by the same
person to avoid personal error in methodology.
The hand length was measured with a calibrated
non stretch tape from distal flexion crease of
wrist to the tip of the middle finger in extension
after nails were trimmed as described by
Amirsheybani et al. (2001)[6]. Data was
expressed as mean ± standard deviation (±SD).

Pearson's correlation analysis was used to
determine the strength of the relationship
between the parameters studied. Students’ T-
test was used to test the significant levels
between the body proportions studied.

Differences were declared significant when
P-value is less than 0.05 (P < 0.05) and
correlation exist when P < 0.001.

RESULTS

The results from the present study show the
mean and standard deviation of height in
medical students was 164.95±10.71, while the
mean and standard deviation of hand length
are 18.56±1.06. In the present study shows that
mean height of male medical students was
173.64±5.0 and female medical students was
156.24±7.1 cm. Mean height of first year
medical students child was 164.95±10.71 cm.
Mean length of hand in male medical students
was 19.24 cms ± 0.80 cm. and female medical
students was 17.89 ± 0.85 cm. Mean hand
length of all the first year medical students was
18.56±1. Our study reveals that mean height
of case who belong to one year of age group
were 8.55 lines more than length of hand. As
age increases the mean length of hand also
increases. In our study age group the height is
approximately 9 times more than length of hand.

Pearson’s correlation analysis was used to and
shows a strong positive correlation, which
means that high X variable scores go with high
Y variable scores.

The results show that height and hand length
was significantly increased with age of the
medical students. (P < 0.05). This shows that
there is a proportional relationship between age
and the parameters studied and an age
dependent increase in height and hand length.

The linear regression equation for estimation of
height from age (years) with hand length shows
there was a positive correlation (p < 0.001)
between height and hand length.

The result shows the multiple regression
equation for estimation of height and hand
length. The multiple linear regressions show a
positive correlation (P < 0.001) of height with
the other parameters used.

The value of R is 0.8229. This is a strong positive
correlation, which means that high X variable
scores go with high Y variable scores.

DISCUSSION

The result of the present study showed that the
dimension of hand length can be associated
with height and can be used in the estimation
of height. The parameters studied, showed a
significant correlation with height, hence these
could be used by law enforcement agents and
forensic scientists in the identification of the
fragmentary dismembered human remains. Since
it has been established that long bones are the
most appropriate specimen for height evaluation
and estimation [25,31], hand length was chosen
for this study as it is part of the long bones of
the body.
It has been shown in this study that there was a significant correlation between height and hand length. The use of anthropometric methods is available in the case of athletes in which the bone area values at different sites of the body are strongly related to muscle strength and parameters related to body size such as height, weight, lean mass, fat mass and body mass index according to Ruff, (2000) and Jasuga et al., (2004)[32,31]. Thus morphometric estimation of height from skeletal size appears to work reasonably well in both normal and highly athletic modern humans [32,31]. Estimation of height using various physical measurements has been attempted by many researchers but the one variable that proves to be consistently reliable in the estimation of height is the hand length [33,34]. The result from the present study shows that hand length can be used to predict height. The present study shows the parameters used to determine height can also be used to determine hand length because there was a 2-tailed significant correlation between hand length and height. In the age group 19-23 years the height is approximately 9 times more than length of hand. This shows that height of any age group is 9 times more than the length of hand. Danborno found that the relationship between hand and foot length and height is strongly significant (P<0.001). When hand and foot were correlated the relationship between hand and foot length was higher in the females than the males, but when hand and foot lengths were compared to height the relationship was stronger in the males than in the females. Multivariate analysis was conducted to see if the height of subjects could be predicted from the lengths of right and left hands and feet. This proved to be effective and provided valuable predictive equations that enable the prediction of height for both males and females, with higher prediction ability in the females than the males [35]. This finding is in agreement with reports from Turkish sample [35, 36] and Indian sample [13].

**CONCLUSION**

The results from the present study indicated that among the 17 – 23 year age group, male had more height than female. As age groups increase the mean length of hand also increase, there is direct relation between length of hand and age groups. Definite proportion also exists between the height and hand length in an individual at all ages, irrespective of the sex. Height of an individual is 9 times the height of hand length. Hand length is a proxy indicator for height when it is difficult or not possible to measure height directly, thus stand as indicator for predicting height among medical students of SKIMS Medical college
