ABSTRACT

Introduction: Lungs are essential organs of respiration. Variations in lobes and fissures of lungs are clinically significant. Awareness of these variations is essential during segmental resections of lung. This study is conducted to observe the completeness of fissures, presence of accessory fissures and accessory lobes of lungs.

Materials and Methods: 100 lungs (50 right and 50 left) from embalmed cadavers and autopsied bodies were studied for the presence of normal fissures, its variations including number of lobes, accessory lobes and accessory fissures.

Results: The right lungs had complete oblique fissure and complete horizontal fissure in 68% and 30% respectively. The left lungs had complete oblique fissure 62%. Oblique fissure was incomplete in 32% of right lung and in 38% of left lung. Horizontal fissure was incomplete in 52% and absent in 18%. 73.3% of incomplete oblique fissure of right lung showed incompleteness posteriorly. In the left lung oblique fissure showed incompleteness anteriorly in 26.3%, in the middle in 21.1% and posteriorly in 52.6%. Horizontal fissure of right lung was incomplete anteriorly in 96.2%.

Accessory fissures were present in 4 specimens (8%) of right lungs and in 1 specimen (2%) of left lungs and accessory lobes were present in 2 specimens (4%) of right lungs.

Conclusion: The fissures in normal lungs enhance uniform expansion of lobes. Absence of fissures can affect the expansion of the lungs. Incomplete fissures may also alter the spread of disease within the lung. Knowledge of accessory fissure and variations in lobes and fissures of lung are important as it may mislead while interpreting in radiology.

KEY WORDS: Accessory, Fissure, Lobes, Lung, Variation.

The inferior border of right lung approximately 7.5 cm behind its anterior end. On the posterior border, it is either at level of 4th thoracic spine or slightly lower. The horizontal fissure separates upper and middle lobes. It passes from the oblique fissure near the mid axillary line horizontally forwards to anterior border of lung, then passes backward to hilum on mediastinal surface. Left lung is divided into superior and inferior lobe by an oblique fissure which extends from the costal to medial surface of lung both above and below the hilum [1].

The visceral or pulmonary pleura adheres closely into pulmonary surface and its interlobar fissure. The fissure can be complete or incomplete. In complete fissure the lobes remain held together only at the hilum by bronchi and pulmonary vessels [Fig.1 and 2]. It is said to be incomplete when there are areas of parenchymal fusion between the lobes or the entire fissure may be absent [2].

Knowledge of anatomy of the fissures of lung and identification of its completeness is essential prior to lobectomy and also for understanding their variable appearances on radiological investigations.

MATERIALS AND METHODS

After obtaining ethical clearance, 100 lungs (50 right and 50 left) procured from embalmed cadavers of Department of Anatomy and autopsy specimens from Department of Forensic Medicine of Government Thoothukudi Medical College were studied for the presence of normal fissures, its variations, number of lobes, accessory lobes and accessory fissures. Completeness of a fissure is determined as per the grading given by Craig and Walker [3]. The measurements were taken with inch tape and photographed.

RESULTS

The right lung was normal with complete oblique fissure in 68% and complete horizontal fissure in 30%. The left lung was normal with complete oblique fissure 62%. In right lung, oblique fissure was incomplete in 32% [Fig: 3] and horizontal fissure was incomplete in 52% and absent in 18% [Fig: 4]. In 38% of left lung, oblique fissure was incomplete. 73.3% of incomplete oblique fissure of right lung showed incompleteness posteriorly. In the left lung oblique fissure showed incompleteness anteriorly in 26.3%, in the middle in 21.1% and posteriorly in 52.6%. Horizontal fissure of right lung was incomplete anteriorly in 96.2%.

Accessory fissures were present in 4 specimens (8%) of right lungs [Fig: 5 & 6] and in 1 specimen (2%) of left lung and accessory lobes were present in 2 specimens (4%) of right lungs [Fig: 6 & 7].

DISCUSSION

Anomalies of lobation of the lungs may be produced by fusion of adjacent lobes to obliterate a fissure, by the occurrence of abnormal fissures or by the aplasia or agenesis of a part of a lung. Horizontal fissure is most commonly incomplete at its anterior end [4].

Each terminal lobe of the endodermal outgrowth together with the surrounding splanchnopleuric mesenchyme constitutes a lung bud from which all the tissues of the corresponding lung and bronchial tree will be derived. Right lung bud possesses three bronchial tubes, while the left has only two. On subsequent development the stem bronchi divide dichotomously. Occasional monopodial branching of the stem bronchi account for the accessory bronchi and lobes [5].

Completeness of a fissure is determined as per the grading given by Craig and Walker. Grade 1- complete fissure with entirely separate lobes; grade 2- complete visceral cleft but parenchymal fusion at the base of the fissure; grade 3- visceral cleft evident for part of the fissure; grade 4- complete fusion of the lobes with no evident fissural line.
Gradation of fissures is important surgically. Ligation of the vessels and bronchi are approached through the depth of the fissures by the surgeons. Grade I oblique fissure makes the approach easy while doing lobectomy and in video assisted thoracoscopic surgery. Otherwise the lung parenchyma has to be dissected to reach those structures leading to preoperative hemorrhage and postoperative complications [6].

Incomplete fissures may also alter the spread of disease within the lung. In patients with incomplete fissures, pneumonia may spread to adjacent lobes through the incomplete fissures. Incomplete fissure may alter the usual patterns of collapse seen in patient with endobronchial lesions. An incomplete major fissure can cause the odd appearance of fluid tracking within the fissure [7].

Accessory fissures can be mistakenly confused with areas of linear atelectasis, pleural scars, or walls of bullae [8]. The fissures in normal lungs enhance uniform expansion of lobes. Absence of fissures can affect the expansion of the lungs.

An accessory fissure is important as it can be mistaken for a lung lesion while interpreting in radiology [9]. In X-ray, incomplete fissure always give an atypical appearance of pleural effusion. Sometimes the accessory fissures are failed to be detected on CT scans, because of their incompleteness, thick sections and orientation in relation to a particular plane. An incomplete fissure is also a cause for postoperative air leakage. The lobes of lungs show partial fusion as a result of incomplete pulmonary fissures [10].

Lymphatics of lung drain centripetally from pleura towards the hilum. Altered course of oblique fissure would mean altered course of visceral pleura, thereby changing the arrangement of lymphatic drainage [11].

CONCLUSION

Awareness regarding anatomical variations is essential for performing lobectomies, segmental resection and interpreting radiological images. Further studies correlating the variations of fissures and lobes of lungs with the bronchopulmonary segments will be significant and has to be carried out on larger extent.
