Diabetes mellitus and medicinal plants—a review

Surendran Surya, Abdul Dhaliya Salam, Dawn Vallikattukuzhiyil Tony, Betty Carla, Ravindrakurup Arun Kumar, Christudas Sunil*

St. Joseph College of Pharmacy, Cherthala, Kerala, India

1. Introduction

Diabetes mellitus (DM) is a chronic metabolic disorder, resulting from insulin deficiency, characterized by abnormal increase in the blood sugar level, altered metabolism of carbohydrates, protein and lipids, and an increased risk of vascular complications[1,2]. Uncontrolled hepatic glucose output and reduced uptake of glucose by skeletal muscle with reduced glycogen synthesis leads to hyperglycemia[3]. Long term damage and failure of different organs were found along with chronic hyperglycemia[2].

As per World Health Organization, DM is a chronic metabolic disorder characterized by common features of chronic hyperglycemia with disturbance of carbohydrate, fat and protein metabolism[4]. There are numerous pathogenic processes involved in the development of diabetes. This includes autoimmune destruction of the β-cells of the pancreas which leads to consequent insulin deficiency and abnormalities that result in resistance to insulin action. Deficiency of insulin on target tissues causes abnormalities in carbohydrate, fat, and protein metabolism.

metabolism. It may be due to inadequate insulin secretion and/or diminished tissue responses to insulin [1,2]. Signs and symptoms of hyperglycemia include polyuria, polydipsia, weight loss, polyphagia, blurred vision, tachycardia, hypotension and wasting [1-5]. Chronic hyperglycemia may also cause impairment of growth, susceptibility to certain infections [2]. Uncontrolled diabetes causes ketoacidosis of different grades and hyperosmolar (nonketotic hyperglycemic) coma. Its cause is obscure but appears to be precipitated by the same factors as ketoacidosis especially those resulting in dehydration [6]. The development of foot ulcer, renal impairment and retinopathy may be considered as long term complications of long-standing diabetes in a patient [7]. Patients with diabetes have an increased incidence of atherosclerotic cardiovascular, cerebrovascular, peripheral and arterial diseases [2]. Hypertension often coexist with diabetes, promoting progressive renal damage [8]. Abnormalities of lipoprotein metabolism are often found in people with diabetes [1].

2. Epidemiology

As of 2010, an estimated 280 million people had diabetes, with type 2 making up about 90% of the cases globally [9]. The incidence of this disease is increasing rapidly and at the end of 2030, the number of cases will be double, as a result of increasing longevity and obesity. Diabetes is more common in developed countries, eventhough there is an increase in the prevalence rate in Asia and Africa. Environmental and genetic factors play an important role in the development of diabetes in varying populations [10].

The incidence of insulin dependent DM ranged from 1.8 to 7.0/100000 per year in Africa, 0.14 to 10/100000 per year in Asia, approximately 3.4 to 36/100000 per year in Europe, 2.61 to 20.18/100000 per year in the Middle East and 7.60 to 25.6/100000 per year in North America and that of non insulin dependent DM ranged from 0.4% to 17.9% in Africa, 1.2% to 14.6% in Asia, 0.7% to 11.6% in Europe, 5.6% to 40% in the Middle East and 7% to 28.2% in North America [11].

3. Etiologic classification of DM

Assigning a type of diabetes to an individual often depends on the circumstances present at the time of diagnosis, and many diabetic individuals do not easily fit into a single class [2]. According to American Diabetes Association [2], diabetes has been classified (Table 1).

4. Pathophysiology of DM

The pathophysiology of diabetes depends on knowledge of the basics of carbohydrate metabolism and insulin action. Carbohydrates from the food are broken down into glucose molecules in the gut and this glucose is absorbed into the bloodstream, elevating the blood glucose levels which results in the secretion of insulin from the pancreatic beta cells. Insulin binding to specific cellular receptors facilitates entry of glucose into the cell. The cell uses glucose for energy production. The increased insulin secretion from the pancreas and the subsequent cellular utilization of glucose results in lowered of blood glucose levels. Lower glucose levels in turn results in decreased insulin secretion. If insulin production and secretion are altered by diseases, blood glucose dynamics will also change. The decrease in insulin production may inhibit glucose entry into the cells resulting in hyperglycemia. Inadequate utilization of pancreatic insulin by the cells also leads to abnormal increase in the blood sugar level. When there is an elevation in the insulin secretion, blood glucose level becomes low (hypoglycemia) as large amounts of glucose enters the cells and little remains in the bloodstream[13].

Excess glucose is stored in the liver and muscles as glycogen. Later, when energy is needed, glycogenolysis converts stored glycogen back to glucose. Triglycerides also formed from excess glucose and stored in adipose tissue which may subsequently undergo lipolysis, yielding glycerol and free fatty acids. The liver also produces glucose from proteins and fat through a process called gluconeogenesis. Normal homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids and amino acids, which maintains a blood glucose level, sufficient to provide an uninterrupted supply of glucose to the brain[14]. The counter-regulatory hormones such as glucagon, catecholamines, growth hormones, thyroid hormones and glucocorticoids also affect the normal blood glucose level (Figure 1)[15].

4.1. Type 1 DM

Type 1 diabetes most commonly develop in childhood and progresses with age. It is called as insulin dependent DM[16,17]. The basic phenomena in the type 1 diabetes is cell–mediated autoimmune destruction of pancreatic beta islet cells. This leads to absolute insulin deficiency and predisposes the individuals to diabetic ketoacidosis (DKA) [18]. Type 1 diabetes is autoimmune in nature, although idiopathic destruction of beta cells which has a tendency to develop ketosis also comes under this group. All the patients with type 1 DM need insulin as a therapeutic agent.

Destruction of beta cells and insulin deficiency in a genetically predisposed individual arise from the environmental factors which triggers an autoimmune process is a main feature of type 1 diabetic patients[16]. Several mechanisms contribute to beta cell destruction[19]. T lymphocytes react against beta cell antigens and cause cell damage. The islets show cellular necrosis and lymphocytic infiltration. The lesion is called as insulitis and locally

Figure 1. Mechanism of action of insulin.
produced cytokines can damage beta cells\textsuperscript{20},

Genetic and environmental modifiers causes dysregulation of the immune system and this will lead to the formation of auto antibodies\textsuperscript{16}. These antibodies may involve in causing the disease or it may be a result of T–cell mediated cell injury and release of normally sequestered antigens\textsuperscript{21}. Autoimmune disorders found with type 1 DM are Graves’ disease, pernicious anaemia etc. in about 10%–20% cases\textsuperscript{22}. Auto antibodies may be found in some patients, even 15 years before the onset of acute disease. This could eventually provide a means of early identification of prediabetics so that they may be treated prophylactically, possibly by immunotherapy\textsuperscript{23}.

The presence of genetic component in type 1 diabetes involves the inheritance of multiple genes to confer susceptibility to the disorder\textsuperscript{18}. Diabetes has a complex pattern of genetic associations, and the susceptibility genes have been mapped to at least 20 loci\textsuperscript{24}. In a human leukocyte antigen–associate susceptible individual, beta cells act as autoantigens and activate CD4+ T lymphocytes, bringing about immune destruction of pancreatic beta cells\textsuperscript{18}.

The environmental factors play an important role in the pathogenesis of type 1 DM\textsuperscript{25}. There is an existence of the environmental modifiers of the disease\textsuperscript{16}. Epidemiologic studies suggest the role of viruses, experimental induction with certain chemicals such as alloxan, streptozotocin, early life factors, vaccinations etc. Recently, it is thought that environmental agents serve as modifiers of genetic susceptibility to autoimmunity\textsuperscript{16,26}.

4.2. Type 2 DM

Type 2 DM previously called non insulin dependent DM or maturity–onset diabetes. It has a late onset and this type comprises about 90% of all cases of diabetes. The two metabolic defects that characterize type 2 diabetes are insulin resistance and inadequate insulin secretion. Type 2 DM is a heterogenous disorder with more complex etiology and is far more common than type 1, but less much known about its pathogenesis\textsuperscript{27}. It is characterized by a slow, gradual onset of hyperglycemia that is often asymptomatic. Elevation in the blood glucose levels results from increasing insulin resistance and impaired insulin secretion leading to relative insulin deficiency. Genetic defects, heredity and certain environmental factors play key role in the development of the disease\textsuperscript{28}.

4.2.1. Genetics

Multifactorial inheritance is the most important factor in the development of type 2 DM\textsuperscript{27}. Genetic defects of insulin signaling pathway and insulin receptor mediates insulin resistance. Children of type 2 patients show the signs of insulin resistance at an early age. Specific point mutation accounts only for a minority (less than 5%) of patients with the insulin resistance\textsuperscript{29}. Analysis of candidate genes have yielded many polymorphisms that associate with type 2 diabetic phenotype, but in most cases the associations have been weak, or the studies were not reproducible\textsuperscript{30}.

4.2.2. Environment

Environmental factors which specifically targets beta cell, triggers the autoimmune process\textsuperscript{16}.

4.2.3. Beta cell dysfunction

Failures of beta cell function leads to inadequate secretion of insulin, the exact genetic mechanism behind the fall in secretion in these cases are unclear. The possibilities involves amylin which forms fibrillar protein deposits in pancreatic islets, glucose toxicity and lipotoxicity in these cases may worsen the islet cell function\textsuperscript{31}.

4.2.4. Insulin resistance

Insulin resistance is defined as resistance to the effects of insulin on glucose uptake, metabolism or storage\textsuperscript{32}. Genetic defects in insulin signaling pathway are not common and if present, are more likely polymorphisms with subtle effects rather than inactivating mutations\textsuperscript{33}. The acquired causes of insulin resistance involves nutrition, physical activity and obesity and these are closely associated with each other\textsuperscript{16}.

4.2.5. Obesity

The link between obesity and diabetes is mediated via effects on insulin resistance\textsuperscript{34}.

4.2.6. Role of free fatty acids

Excess circulating free fatty acids are deposited in the muscle and liver tissues of obese individuals leading to an increase in the level of intracellular triglycerides. These triglycerides and products of fatty acid metabolism are potent inhibitors of insulin signaling and result in an acquired insulin resistance state. A decrease in activity of key insulin–signaling proteins mediates the lipotoxic effects of free fatty acids\textsuperscript{35}.

4.2.7. Role of adipokines

A variety of proteins released into the systemic circulation by adipose tissue have been identified. Dysregulation of adipokine secretion may be one of the mechanisms by which insulin resistance is tied to obesity\textsuperscript{36}.

4.2.8. Nutrition

Nutrition plays an important role in the development of obesity, insulin resistance and type 2 diabetes. Increase in the total caloric intake leads to obesity\textsuperscript{37}.

4.2.9. Physical activity

Physical activity is one of the principal therapies to acutely lower blood glucose in type 2 diabetes due to its synergistic action with insulin in insulin–sensitive tissues\textsuperscript{38}. Essential
hypertension is a common risk factor in patient with type 2 DM. Some studies shows tht regular physical activity lower blood pressure in person with type 2 DM[39,40]. Weight loss leads to decrease in insulin resistance which may be most beneficial early in progression of the disease[41].

5. Diagnosis of diabetes and prediabetes

Blood tests are used in the diagnosis of diabetes and prediabetes. Type 2 diabetes may have no symptoms. Currently, the American Diabetes Association recommends routine screening for type 2 DM every 3 years in all adults starting at 45 years of age[41]. Lab analysis of blood is needed to ensure that the test results are accurate. Glucose measuring devices used are not accurate enough for diagnosis but may be used as a quick indicator of high blood glucose. Testing enables to find and treat diabetes before complications occur and to find and treat prediabetes. This can delay or prevent type 2 diabetes from developing. Mass screening programmes have used glucose measurements of fasting, post prandial or random blood sample[42].

- An A1c test, also called the hemoglobin A1c/HbA1c/ glycohemoglobin test;
- A fasting plasma glucose test;
- An oral glucose tolerance test[43].

Glycated hemoglobin is better than fasting glucose for determining risks of cardiovascular disease and death from any cause[44]. Not all tests are recommended for diagnosing all types of diabetes. The random plasma glucose test is sometimes used to diagnose diabetes during a regular health checkup and if it measures above 200 µg per deciliter then the individual also shows the symptoms of DM[43].

Main symptoms of diabetes include increased urination, increased thirst, fatigue, weight loss, blurred vision, and diabetic dermoadromes. Any test used to diagnose diabetes requires confirmation with a second measurement unless clear symptoms of diabetes exist[45].

Figure 2 provides the blood test levels for diagnosis of diabetes for a nonpregnant adults and diagnosis of prediabetes[46].

5.1. Urine testing

Urine tests are cheap and convenient, but the diagnosis of urine testing cannot be based on urine testing alone since there may be false positives and false negatives. They can be used in population screening surveys. Urine is tested for the presence of glucose and ketones.

5.1.1. Glucosuria

Benedict’s qualitative test detects any reducing substance in urine and dipstick method which is more specific and sensitive method.

5.1.2. Ketonuria

Rothera’s test and Strip test are performed for the detection of ketone bodies[46].

6. Clinical features of DM

6.1. Type 1 DM

Patients of type 1 DM usually manifest at the early age, generally below 35 years of age. The onset of symptoms is often abrupt. At presentation, patients have polyuria, polydipsia, polyphagia, fatigue, and weight loss. Type 1 diabetics are often first diagnosed when they present with DKA. The symptoms could be dry skin, numbness or lack of sensation in the feet, rapid deep breathing, vomiting and abdominal pain (Figure 3).

6.2. Type 2 DM

This form of diabetes generally manifests in middle life or beyond, usually above the age of 40. The onset of symptoms in type 2 DM is slow and insidious. Generally the patient is asymptomatic when the diagnosis is made on the basis of glycosuria or hyperglycemia during physical examination, or may present with polyuria and polydipsia. Major symptoms include tiredness, lethargy, itching, skin infections, blurred vision, mood swings, headache, dizziness and leg cramps.
Metabolic complications like ketoacidosis are infrequent[5].

7. Complications of DM

7.1. Acute metabolic complications

7.1.1. DKA

It is one of the acute metabolic complication of diabetes. DKA is characterized by uncontrolled hyperglycemia, acidosis and increased level of ketone bodies. Decreased effective insulin concentration and increased concentration of counter regulatory hormone lead to ketosis. Patients with ketosis have autoimmune type 1 diabetes[47]. Infection is the most common precipitating factor in the development of DKA[48].

7.1.2. Hyperglycemia hyperosmolar state (HHS)

Differences in insulin availability and dehydration due to diuresis distinguishes HHS from ketoacidosis[47]. Sustained hyperglycemic diuresis results in severe dehydration. The patient is unable to drink sufficient water to maintain urinary fluid loss. Plasma osmolality and blood sugar level is very high. HHS is usually seen in patient with type 2 DM[49,50]. Insulin levels in HHS prevents lipolysis and ketogenesis[51].

7.1.3. Hypoglycemia

In those treated for diabetes, a diagnosis of hypoglycemia can be made based on the presence of a low blood sugar alone. The episode may develop in patients with type 1 DM. Alteration of consciousness occurs or even it may lost in extreme cases, leading to permanent brain damage, rebound hyperglycemia and death. The variety of interactions may cause identification difficulty in many instances[52].

7.1.4. Respiratory infections

In diabetes patients, alteration in host defense mechanism leads to hyperglycemia, inflammation and increased susceptibility to infections. There is an impairment in the function of respiratory epithelium and ciliary movement[53,54].

7.1.5. Periodontal disease

Diabetes is also associated with gum diseases and may make diabetes more difficult to treat[55,56].

7.2. Late systemic complications

7.2.1. Atherosclerosis

DM of both type 1 and 2 accelerates the development of atherosclerosis so that consequent lesions appear earlier than in the general population and associated with ulceration, calcification and thrombosis[57].

7.2.2. Diabetic microangiopathy

It is characterized by the basement membrane thickening of small blood vessels and capillaries. Thickening is mainly due to the increased glycosylation of haemoglobin and other proteins like collagen and basement membrane material. The pathogenic basis behind microangiopathy is the recurrent hyperglycemia[58].

7.2.3. Diabetic nephropathy

Specific renal functional and morphological alterations lead to diabetic nephropathy and are characterized by hyper filtration of glomerulus, albuminuria, renal hypertrophy etc. Initially there is an elevation of renal plasma flow and glomerular filtration rate. Glomerular hypertension and renal insufficiency accelerates kidney failure[59].

7.2.4. Diabetic retinopathy

It is a leading cause of blindness. Progression is from mild non proliferative abnormalities to severe proliferative diabetic nephropathy[60].

7.2.5. Diabetic neuropathy

It is heterogeneous and may affect all part of the nervous system, but symmetric peripheral neuropathy is most characteristic. It may be local or diffuse[61].

8. Therapy for DM

Diet therapy is important for the prevention as well as the treatment of all stages of type 2 diabetes. Till it continues to remain high controversial and poorly understood. In majority of the individuals with type 2 DM, if obesity seems along with hyperglycemia, weight reduction is the major goal of dietary therapy[62].

Exercise helps to prevent type 2 DM and control all types of diabetes cases. Muscular sensitivity to insulin can be improved by physical activity. The mechanisms involved are increased blood flow to the tissues and reduced free fatty acid and intra abdominal fat level[63].

8.1. Oral hypoglycemic drugs

8.1.1. Sulfonylureas and the newer glitazides

Sulfonylureas have been used to treat type 2 diabetes since 1942 and require functional pancreatic beta cells for their hypoglycemic effect[64,65]. They have an islet beta cytotropic activity[66]. The meglitinides are relatively new class of insulin secretagogues[67]. Both of them act by inducing insulin secretion. The glitazides have a more rapid action of onset and shorter duration of effect than sulfonylureas and are given before a meal to stimulate prandial release of insulin. The average decrease in HgA1c is 1–2 mg/dL. Both these medications can lead to hypoglycemia and weight gain[68].

8.1.2. Biguanides—metformin

They stimulate peripheral utilization of glucose, increase the sensitivity of muscle to insulin action and reduce the intestinal absorption of glucose and leads to an average decrease in HgA1c of 1–2 mg/dL by reducing hepatic gluconeogenesis[69]. Patients of renal or hepatic disease, hypoxic pulmonary disease or heart failure are predisposed to lactic acidosis because of reduced drug elimination or
reduced tissue oxygenation. Alcohol ingestion may also precipitate lactic acidosis[70]. Metformin is an insulin sparing agent and does not increase weight or provoke hyperglycemia. It should be given first line in obese type 2 diabetes[71].

8.1.3. α-glucosidase inhibitors (acarbose and miglitol)
α-Glucosidase inhibitors act by inhibiting absorption of carbohydrates. Acarbose also inhibits α-amylase. On average lower HbA1c by 0.5–1.0 mg/dL. Its use is limited by disagreeable gastrointestinal symptoms[72]. These drugs are contraindicated in patients with inflammatory bowel disease and renal impairment. Acarbose should be used with caution in the presence of hepatic diseases[67].

8.1.4. Thiazolidinediones (rosiglitazone and pioglitazone)
Thiazolidinediones appears to act by binding to the peroxisome proliferator activator receptor-γ[73,74]. They increase the peripheral sensitivity to insulin, reduce hepatic glucose output, and increase peripheral glucose disposal[68]. The overall effect on HbA1c is a 1% to 1.5% reduction and they increase high density lipoprotein cholesterol by 3–9 mg/dL[75]. Glitazones are contraindicated in children, lactating mother, in liver and heart failure cases[76].

8.1.5. Incretin mimetic (exenatide)
Exenatide is a long acting glucagon–like peptide–1 analogue[77]. It enhances glucose–dependent insulin secretion. Food and Drug Administration approved for use as an adjunct for those failing oral agents. Major adverse effects include nausea, vomiting and hypoglycemia. It has similar efficacy to bedtime insulin (without the weight gain) when added to failing oral regimen, but substantially more expensive[71].

8.1.6. Amylin analogue (pramlintide)
It suppresses postprandial glucagon secretion and slows gastric emptying. The level HgA1c decreased on average 0.1–0.6 mg/dL. Because of the risk of hypoglycemia insulin doses should be decreased by 50% or more[78].

8.2. Insulin
Increase in blood glucose level promotes both synthesis and secretion of insulin from beta cells. Insulin has many formulations. Indications for starting insulin include new diagnosis of severe, symptomatic hyperglycemia, co-morbid conditions such as renal or liver disease, congestive heart failure, active infection that may control difficult with oral medications, pregnancy, diabetic coma, precoma, and intolerance to oral medications. Formulations of insulin varies in their time to peak activity and duration of action. Patient may need only long–acting insulin in the early stages of type 2 DM. As diabetes progresses will likely need meal time and long–acting insulin to adequately control sugars. Typical starting insulin dose is 10–20 units/d. Therapy has to be individualized and no fixed schedule is possible. Insulin use results in weight gain, allergy, resistance and can lead to hypoglycemia[78,79].

9. Plant remedies in the management of DM
Herbs are used by the mankind since its origin on the earth for alleviating ailments and for the maintenance of general health. Since ancient times, plants remained major natural resource in the world[80]. Mainly tribes provided the knowledge base regarding medicinal properties of the herbs and these plants have a great demand in both developed and developing countries[81]. World Health Organization estimated that 80% world’s population relies on traditional medicines to meet their primary health care needs, most types of which use remedies from plants. Even the modern pharmacopoeia still contains at least 25% of drugs derived from plants and many others which are semisynthetic, built on prototype compounds isolated from plants[80]. Recent studies suggest that over 9000 herbs have known medicinal applications among various cultures and countries. Different indigenous medicinal systems such as Allopathy, Siddha, Ayurveda and Unani use several plant species for the treatment of diseases[82,83]. In recent times, it is imperative that all systems of traditional plant medicines prevailing in the world need to be encouraged if we intend to find cure for those diseases where modern synthetic medicines have failed or where the modern synthetic drugs are beyond the reach of the poor nations[84]. In India, traditional plant remedies have been used in the treatment of various diseases since the time of Charaka and Shushrutha[85]. India has a special position in area of herbal medicines, since it is one of the few countries which are capable of cultivating most of the important plants used both in modern and traditional system of medicine[85]. Demand for herbal medicine sector is growing fast, increasing by 12%–15% value per year[80].

DM is a disease characterized by impairement of body’s normal ability to metabolise or utilize food. During Second World War, when insulin was not available in many countries, research was made for an insulin substitute from plant sources. Many plant species are known in folk medicines of different cultures which have been used for their hypoglycemic effects, a property which reduces the blood sugar concentration. These plants have been found to be useful for the treatment of diabetes[84]. From ancient times, a number of medicinal plants and their formulations used in the treatment of diabetes in Ayurvedic and ethnomedicinal practices[82]. Various synthetic drugs developed for the treatment of diabetes, but their use is limited because of their side effects and cost. The popularity of plant medicines due to their lesser side effects and toxicity, led to an increase in the number of herbal drug industries. Indian flora provides great possibilities for the development of new compounds with important medicinal applications. The phytoconstituents showing hypoglycemic effect includes flavanoids, alkaloids, carbohydrates, glycosides, steroids, peptides, lipids etc[86]. Numerous herbs remain potent candidates for antidiabetic drug development. Clinical data begins to emerge, which supports antidiabetic properties of these drugs[87].

Medicinal plants list with proven antidiabetic and related beneficial effects and of herbal drugs used in the treatment of diabetes are compiled in Table 2.

Acknowledgements

Authors are thankful to the Indian Council of Medical Research, New Delhi for providing Senior Research Fellowship (Grant No. 45/31/2010/BMS/TRM) and St. Joseph College of Pharmacy, Cherthala, Alappuzha, Kerala for their kind and support in preparing this review article.

Comments

Background

Diabetes is one of the major health and development challenges of the 21st century. According to the International Diabetes Federation, there are currently 371 million people living with diabetes and another 28 million people are at high risk of developing the disease. Apart from conventional allopathic medicines, traditional/alternative therapy plays a significant role in treating DM.

Research frontiers

The authors have put the effort and compiled all the information about DM and plants showed antidiabetic effect which shall be a report of plants used in the treatment of DM.

Related reports

It is not a research work but the authors have summarized the information about DM and medicinal plants.

Innovations & breakthroughs

Authors have attempted to compile the types, pathophysiology, complications and treatment of DM. All this information will help researchers to explore its scientific evidence based on modern era.

Applications

It will be significant to know traditional uses and phytoconstituents present in different plants to expand unexplored area by scientific evaluation.

Peer review

This is a good review paper in which the authors have reviewed about DM and the role of medicinal plants for the treatment. I recommend this article to be published.
