Abstract
Introduction: Gastrocnemius has a medial and lateral belly. It joins with soleus to get inserted as the Achilles tendon. Accessory heads of gastrocnemius can give rise to popliteal artery entrapment syndromes.

Materials and Method: 60 formalin embalmed lower limbs mere meticulously dissected to see for any variation in number of heads and nerve supply of Gastrocnemius.

Observations: 15% limbs showed accessory heads of gastrocnemius. 8.34% showed 4 heads and 6.66% showed 3 heads. Length of Achilles tendon in limbs with variation ranged from 6.1 cm to 12.8 cm.

Conclusion: Knowledge of accessory heads of gastrocnemius will help the radiologist during imaging studies in cases of popliteal entrapment syndromes and neurovascular compression.

Keywords: Gastrocnemius tertius, Accessory head of gastrocnemius, Popliteal artery entrapment syndrome, Calf injury, Additional heads of gastrocnemius.

Introduction
The calf is made of bipennate muscle gastrocnemius and multipennate muscle soleus. Gastrocnemius has a medial head known as caput mediale and a lateral head known as caput laterale.¹ Medial head takes origin from posterior surface of femur above medial condyle and lateral head arises above the lateral condyle. Both heads of gastrocnemius fuse to form a single belly which together with soleus forms the Achilles tendon. The Achilles tendon gets inserted on the dorsal surface of calcaneum.

The word gastrocnemius is derived from Greek words gastro and kneme meaning stomach and leg respectively. The bulging of the calf mimics the bulging of stomach, so it is also called ‘stomach of leg’.²

The tibial nerve supplies the gastrocnemius muscle. It is strong plantar flexor of foot. Soleus acts to initiate walking while gastrocnemius is muscle used in running.

Heads of gastrocnemius form the inferolateral and inferomedial boundaries of popliteal fossa.

Close proximity to Tibial nerve and popliteal vessels in popliteal fossa makes any variant anatomy of gastrocnemius as a differential diagnosis in neurovascular compressions and entrapment syndromes.³

Materials and Method
Meticulous dissection of 60 formalin embalmed lower limbs was done. Any variation in number of heads, origin, insertion and nerve supply of gastrocnemius muscle is noted. Length of the heads of gastrocnemius and Achilles tendon are measured with vernier caliper and measuring tape as applicable. Relation of the popliteal artery to the additional heads of gastrocnemius was noted.

Result
Additional head of gastrocnemius was seen in 9 (15%) lower limbs. 3 cadavers showed bilateral variation (10%). 2 right sided and one left sided lower limb showed unilateral variation. 4 heads of gastrocnemius (Fig. 3) were seen in 5 (8.34%) limbs. 2 cadavers showed 4 heads bilaterally. One right limb demonstrated 4 headed gastrocnemius. 3 heads of gastrocnemius (Fig. 1 and 2) were seen in 4 (6.66%) limbs. One cadaver showed bilateral 3 heads of gastrocnemius. One right and one left side limb showed 3 heads of gastrocnemius. All the heads of gastrocnemius were supplied by tibial nerve. No variation in course of sural nerve was noted. The popliteal artery was seen passing between the accessory medial head and normal medial head of gastrocnemius in 2 cadavers (Fig. 3).

A single belly was formed by joining of all heads of gastrocnemius. This muscle belly joined with belly of soleus to form the Achilles tendon, which inserted on posterior surface of calcaneum. Length of the heads of gastrocnemius before forming common tendon and length of Achilles tendon is tabulated in Table 1. Maximum length seen for medial and lateral bellies are 7.5 cm and 9 cm respectively. Length of Achilles tendon of limbs with additional heads of gastrocnemius ranged from 6.1 cm to 12.8 cm.

**Discussion**

### Embryological reasoning:
Gastrocnemius muscle embryologically originates from the calcaneum blastomere and then it migrates upwards by ascending towards the inferior epiphysis of femur. Before termination on femur it splits into medial and lateral bellies. Any variant mode of embryological migration and termination may result as variation in number of bellies and attachments.(3)

Gastrocnemius is the superficial calf muscle. It originates as medial and lateral heads. The medial head is more commonly injured. Medial head of gastrocnemius sprain is also called ‘Tennis leg’ as it is frequently seen in tennis players. Risk of strain of gastrocnemius is more as it crosses two joints (knee and ankle) and has type two fast acting muscle fibers. Strain of gastrocnemius is called ‘coup de fouet’ or snap of a whip.(4)

Sookur et al(5) in a study of variations of muscles of lower limb state that variations of medial and lateral heads of gastrocnemius are due to anomalous origins and accessory slips. Medial and lateral heads of gastrocnemius take origin from posterior surface of femur, above the condyles and from the capsule of the knee joint. Additional medial head may arise from intercondylar notch instead of medial condyle. Additional slips may arise from intercondylar notch and pass between popliteal artery and vein to get inserted into medial head. Lateral head may have a more medial origin on posterior surface of femur, but lateral to popliteal artery. Additional slips may pass anterolateral to popliteal vessels and insert in the lateral head.

In a study of gastrocnemius in Nigerian population, Ashaolu et al(3) give a 51.7% incidence of four headed gastrocnemius and 13.3% incidence for 3 headed gastrocnemius. These figures are more than our study where we got incidence of four-headed gastrocnemius as 8.33% and three headed gastrocnemius as 6.66%. Knowledge of such variations will help during popliteal nerve blocks and autografting of gastrocnemius muscle.

Shinde et al(6) in a study of soleus muscle report 8% cases of accessory head of soleus. One limb showed three-heads of gastrocnemius with an accessory head of soleus. This condition is known as gastrocnemius tertius. Coexistence of gastrocnemius tertius and accessory soleus is considered a rare variation.

Yildirim et al(7) report a case of bilateral gastrocnemius tertius with unilateral accessory head of soleus. Accessory head of gastrocnemius can lead to entrapment syndromes in popliteal fossa. Decrease in pulse of distal arteries on passive dorsiflexion suggests popliteal artery entrapment, while pain and tenderness in popliteal fossa points towards nerve compression in the popliteal fossa.

Calf injuries are one of the most common muscle injuries of leg. Gastrocnemius acts to flex the leg at knee joint and plantar flex the foot at ankle joint. Gastrocnemius injury is considered high risk because it crosses two main joints, the knee and ankle. Calf injuries occur with strenuous exercise and also on innocuous movements in middle aged people with sedentary lifestyle. Differential diagnosis for calf injury are gastrocnemius tear, thrombophlebitis, soleus tear, Achilles tendon rupture, and posterior compartment syndrome. Pain in the medial head of gastrocnemius...
just above the musculotendinous junction with palpable
tenderness are clinical signs to diagnose gastrocnemius
tear.\(^{(8)}\)

A case report of four headed gastrocnemius was
given by Rodrigues et al.\(^{(9)}\) They describe the medial
head of gastrocnemius splitting into three heads. The
multiple heads join with the lateral head to form the
Achilles tendon. The sural nerve was seen entrapped
between the multiple heads of gastrocnemius. Sural
nerve is primarily a sensory nerve but they state that
considering some communication with tibial nerve in
leg, motor loss is also reported along with sensory loss
in case of entrapment. No variation in course of sural
nerve was seen in our study.

Popliteal entrapment syndrome was first reported
by Anderson Stuart. Unilateral calf pain in a athletic
young patient is a symptom seen in popliteal artery
entrapment syndrome. Accessory medial head of
gastrocnemius compressing the artery in popliteal fossa
is the most common cause. Stenosis of the artery and
early atherosclerotic changes may be seen in chronic
cases. Surgical intervention to relieve the compression
is considered. The popliteal artery is surgically
decompressed with myotomy. This is followed by
embolectomy and prophylactic fasciotomies.\(^{(10)}\)

In a study of patients with entrapment syndromes,
Rosset E et al.\(^{(11)}\) found the popliteal artery was
susceptible for compression in cases of accessory heads
of gastrocnemius. CT and MRI were used to define the
muscular origin of popliteal compression. Higher
insertion of gastrocnemius, presence of a fibrous band
linking the medial and lateral head of gastrocnemius
and muscular hypertrophy were causes for arterial
compression.

Popliteal artery entrapment syndrome has been
reported due to aberrant course of popliteal artery or
accessory heads of gastrocnemius or plantaris muscle
compressing a normal popliteal artery. The range of
prevalence of popliteal artery entrapment syndromes is
0.16 to 3.5\%. The syndrome is classified as type I in
case of an aberrant course of popliteal artery, type II in
case of an accessory medial head of gastrocnemius
compressing the popliteal artery with a normal course.
Type III anomaly has an accessory slip from the medial
head of gastrocnemius, forming a sling around the
popliteal artery and in Type IV a popliteal artery with
normal course gets compressed by passing deep to the
poplitoeus muscle. Any of type I to IV anomaly with
popliteal vein involvement is called type V. Type VI is
popliteal artery compression due to a hypertrophied
gastrocnemius muscle.\(^{(12)}\) Our study shows the popliteal
artery passing between the accessory and normal
medial heads of gastrocnemius in two cadavers (Fig. 1).
This condition is seen in type II popliteal artery
entrapment syndrome.

Radic et al.\(^{(13)}\) describe three cases of popliteal
artery entrapment syndrome. Accessory head of
gastrocnemius compressing the popliteal artery was
reported. Intermittent claudication on physical activity
is seen in young adults. Soldiers and athletes are more
likely to succumb to popliteal artery entrapment
syndromes as their muscles are well toned and
enlarged. Any accessory muscle forming the boundary
of popliteal fossa may lead to compression of the artery.

Conclusion
Gastrocnemius injuries have been one of the
leading causes of calf injuries. Medial head of
gastrocnemius is more commonly involved. Accessory
heads of gastrocnemius have given rise to entrapment
syndromes in the popliteal fossa. Our study gives a 15\%
incidence of accessory heads of gastrocnemius.
Bilateral variation is seen in 10\% cadavers. Three (6.66\%)
and four (8.33\%) headed gastrocnemius muscles are
reported. Knowledge of additional heads of
gastrocnemius is important while autografting and
using imaging techniques for entrapment syndromes.
