ABSTRACT

Objective. To describe the case report of a parasitized dog with Spirocerca lupi in Yucatan, Mexico, as well as report cases registered in two laboratories during 18 years of parasitological and necropsy studies (2000-2017). Materials and methods. A case study is reported, with necropsy, histological and parasitological findings. Likewise, a retrospective study of cases reported in two laboratories where necropsies and faecal Flotation techniques (centrifugal and McMaster) were performed. Results. At the necropsy of the dog, three esophageal nodules were observed, which showed nematodes of S. lupi during the incision of the mass. The histological study showed an eosinophilic granuloma that contained the nematodes at its center, surrounded by a moderate inflammatory infiltrate formed by neutrophils, eosinophils, lymphocytes, plasma cells and macrophages, delimited by a capsule of fibrous connective tissue. In the retrospective study, prevalence of 0.18 and 0.48% were found by coprological tests and necropsy study, respectively. Conclusions. Spirocerca lupi is present in dogs from Yucatan, Mexico with low prevalence, producing in the esophagus of dogs lesions characterized by eosinophilic granulomas. The need to include this pathology in the differential diagnosis of esophageal and respiratory problems in dogs is disclosed.

Keywords: Coprological study, dog, eosinophilic granuloma, necropsy (Source: CAB, MeSH).

RESUMEN

Objetivo. Se describe el caso de un perro parasitado con Spirocerca lupi en Yucatán, México, y además, se reportan los casos registrados en dos laboratorios durante 18 años de estudios parasitológicos y de necropsias (2000-2017). Materiales y métodos. Para el primer caso, se incluyen hallazgos de necropsia, histológicos y parasitológicos. Para los estudios retrospectivos se realizaron necropsias y estudios coprológicos de Flotación Centrifugada y de McMaster. Resultados. En el paciente de caso, durante la necropsia se observaron tres nódulos esofágicos que al realizar la incisión de los mismos, se visualizaron nematodos que correspondieron a S. lupi. En el estudio histológico se observó un granuloma eosinofílico que en su interior contenía el nematodo rodeado por un infiltrado inflamatorio moderado que estaba constituido por neutrófilos, eosinófilos, linfocitos, células plasmáticas y macrófagos; delimitado por una cápsula de tejido conectivo fibroso. En el estudio retroespectivo se encontraron prevalencias de 0.18 y 0.48% mediante pruebas coprológicas y estudios de necropsias, respectivamente. Conclusiones. Spirocerca lupi se encuentra presente en perros de Yucatán, México. Por lo tanto, sería importante considerar esta patología para el diagnóstico diferencial de problemas esofágicos y respiratorios en caninos.

Palabras clave: Estudio coprológico, granuloma eosinofílico, necropsia, perro (Fuente: CAB, MeSH).
INTRODUCTION

Spirocercosis is a disease caused by the nematode *Spirocerca lupi* (Rudolphi 1809). The dog is infected through the consumption of beetles, birds or small reptiles. The migratory larva causes hemorrhage, aortic stenosis, endarteritis, aneurysm or rupture of the aorta. Clinical signs of infection are regurgitation, vomiting, cough, dyspnea, weight loss and sudden death from damage to the aorta. Adult nematodes form nodules mainly in the esophagus, but occasionally they can occur in the wall of the stomach (1).

Due to larval migration, nodules or granulomas can form in other regions such as in thoracic organs, intestinal tract, urinary organs and in the connective tissue of the skin (2). Sarcomas can develop from the granulomas (3).

Spirocercosis is diagnosed by the history and clinical signs, coproparasitoscopic and molecular diagnosis, thoracic image, esophagoscopy and necropsy (4-5).

Spirocercosis caused by *S. lupi* occurs mainly in canines, and is predominant in tropical and subtropical areas. The majority of cases are reported in Israel, Italy, Greece, Turkey, India, Pakistan, Kenya and South Africa (6-7). In the American continent it has been reported in the United States, Brazil and Mexico (8-9).

In Querétaro, Mexico, *S. lupi* has been reported in dogs with a prevalence of 4.5% (9). In Yucatan, Mexico, Quiñones-Avila et al (10) were the first to report the presence of two dogs with *S. lupi* at the necropsy of 38 dogs (prevalence of 5.3%) and showed the importance of this parasite in dogs from the state of Yucatan.

Since this finding, in Yucatan, no case report of this nematode in dogs has been published. Therefore, the present study aims to describe the pathological case of a dog parasitized with *S. lupi* in Yucatan, as well as the report of cases in two laboratories during 18 years of parasitological and necropsy studies (2000-2017).

MATERIALS AND METHODS

Background. The report corresponds to a case study, with necropsy, histological and parasitological findings. As well as the retrospective study of cases reported in the Pathology and Veterinary Parasitology laboratories of the Campus of Biological and Agricultural Sciences of the Autonomous University of Yucatan (CCBA-UADY).

For the case study, a 12-year-old creole dog was received for a necropsy study. The dog had a history of regurgitation, vomiting and weight loss, was born in Merida, Yucatan, Mexico and never left the state of Yucatan. The state of Yucatan is located at a latitude of 19° 31’ - 24° 38N and a longitude of 87° 22’ - 90° 25’ W. The climate is tropical sub-humid with rains in summer. The maximum ambient temperature varies from 35 to 40 °C and the minimum from 10 to 16 °C, with an average ambient temperature of 27 °C. The relative humidity varies from 65 to 90%, with an average of 80% and annual pluvial precipitation of 1,000 mm. Two annual seasons are presented: rain (from June to November) and dry season (from December to May) (11).

Diagnosis of the nematode and histopathological test. At the necropsy of the dog, three oesophageal nodules were observed. Incisions were made with the help of a scalpel blade to allow the exposure of the parasites. The parasitic nematodes were recovered alive and counted and identified with the help of a stereoscope microscope. The collected nematodes were maintained in 95% ethanol (12) and were identified according to Bowman et al (13).

Additionally, samples of the nodular lesions in the esophagus were collected and transferred to a wide-mouth plastic bottle with 10% buffered formalin with pH of 7.2, and maintaining the fixation sample ratio of 1:10. The vial was labeled and kept for 24 h for fixation.

The sample was processed using the paraffin embedding technique and Hematoxylin-Eosin staining. For this, the sample was dehydrated with different consecutive solutions of ethyl alcohol. They were then clarified with xylol and impregnated in paraffin until cooled. Once the paraffin was solidified and the cube formed, serial cuts of 5μm thickness were made, stained with Hematoxylin-Eosin and mounted with synthetic resin. Finally, the sample was revised with the aid of an optical microscope (14).

Retrospective study. To know the presence of cases of *S. lupi* in dogs in southeastern Mexico, the archives of the Parasitology and Veterinary Pathology laboratories of the CCBA-UADY were reviewed from January 2000 to December 2017. Additional information was also obtained from the positive cases such as the origin of the animals, age, breed and the excretion of eggs per gram of feces.

During the period of the retrospective study, 1,631 coprological studies of faecal samples from dogs were performed using the Centrifugal Flotation and McMaster techniques (12). The eggs of the nematodes were identified using the morphological descriptions and sizes described by Bowman et al (13). Also, in this period, 835 necropsies of dogs were performed according to the methodology described by Schuenneman and Constantino (15).

RESULTS

During the necropsy of the dog, three nodules were observed in the esophagus (Figure 1), which showed reddish-colored adult nematodes during the incision of the nodular masses (Figure 2). The macroscopic lesions were located in the last third of the esophagus where each nodule had adherence to the wall of the esophagus, with one growing towards its lumen causing stenosis. In an esophageal region adjacent to a nodule, saccular dilatation was found. The nodules measured between 4 and 3.5 cm long, 2.5 and 3 cm wide and 2 and 3 cm high; and had firm to hard consistency. The nodules had a large central cavity, full of nematode parasites (reddish and whitish), surrounded by cell detritus and delimited by a fibrous connective tissue capsule that sometimes appeared calcified; in the three nodules a fistula was found that opened towards the lumen of the esophagus.
From the three nodules, 12 bright red adult nematodes were recovered, of which seven were males and five were females (Figure 3). The nematodes were classified as *S. lupi* (Figure 3). Males measured $4.2 \pm 0.7$ cm long and $1.0 \pm 0.2$ mm wide and females $7.0 \pm 0.3$ cm long and $1.5 \pm 0.2$ mm wide. The terminal part of the male presented in spiral form with lateral wing and papilla, as well as unequal spiracles. In the female, the vulva opens near the end of the esophagus and the uterus contains thick-covered eggs.

In the centrifugal flotation coprological study of the last case of the parasitology laboratory, *S. lupi* eggs were observed with a wide cover and with the presence of a larva with dimensions of $32.0 \pm 1.8 \mu$ of length x $12.2 \pm 1.6 \mu$ of width (Figure 4).

In the tissue sections esophageal nodule with eosinophilic granuloma were identified. In the central part of the nodule a parasitic structure of a nematode was identified, surrounded by a severe inflammatory infiltrate formed by neutrophils, eosinophils, lymphocytes, plasma cells and macrophages; which are delimited by a capsule of fibrous connective tissue formed by a large number of fibroblasts, fibrocytes and collagen fibers (Figure 5).

In the archives of the Veterinary Parasitology laboratory at the CCBA-UADY, 1631 coprological tests of dog feces samples were performed using the Centrifugal Flotation and McMaster techniques. Three cases of *S. lupi* were found, with a prevalence of 0.18% in feces. Also, the archives of the Animal Pathology laboratory at the CCBA-UADY from 2000 to 2017 were reviewed. In this period, 835 necropsies of canines were carried out and four dogs...
with oesophageal nodules containing adult nematodes of *S. lupi* were found, which correspond to a prevalence of 0.48%. All positive dogs reported in both laboratories came from the state of Yucatan, with no history of leaving the state.

Table 1 shows the cases of dogs diagnosed with *S. lupi* in the Parasitology and Veterinary Pathology laboratories of the CCBA-UADY from 2000 to 2017.

**DISCUSSION**

Spirocercosis has a worldwide distribution; however, is predominant in tropical and subtropical regions (6). The infection depends on the density of the dog population and the degree of interaction between the dog and the paratenic and intermediate hosts (mainly coprophagous beetles). The prevalence of this parasitic disease is variable and the majority of cases are reported in the Southeastern United States, Brazil, South Africa, Kenya and the Middle East (6,16,17).

Necropsy studies for the diagnosis of *S. lupi* in dogs have been carried out in different parts of the world, with prevalences of 14% in South Africa (16,18), 40.0% in Bangladesh (19), and 14.2% in Spain (20). In the present study, low prevalences of 0.18 and 0.48% were found, diagnosed in coprological tests and necropsies, respectively. These prevalences of *S. lupi* in dogs are also low compared to previous studies in Yucatan and Queretaro, where prevalences of 4.5% (9) and 5.3% (10) were found, respectively. This tendency to diminish the cases of *S. lupi* in dogs from Yucatan is probably associated to the constant use of anthelmintics and especially macrocyclic lactones in dogs (21), which have been shown to be effective to control this nematode (6,22).

Spirocercosis occurs mainly in dogs from rural areas or exposed to paratenic hosts. In Greece it was shown that dogs with owner presented lower prevalence (10%) of *S. lupi* compared with dogs that are used for hunting (21%) (23). In the present study it was not possible to investigate the origin of the dogs; however, most of the positive dogs were of criollo breed and adopted by their owners. This condition might favor exposure to the intermediate and paratenic hosts due to the habit of searching food in streets. In Yucatan, Mexico, different species of coprophagous beetles have been reported and the species *Canthon leechi* has preference for dog feces (24). In future studies it will be necessary to study the role of coprophagous beetles within the transmission cycle of *S. lupi*.

Different studies indicate that the age of dogs is not a factor associated with infection with *S. lupi* (6). However, in this study positive dogs for *S. lupi* were adult or geriatric animals aged 4 to 12 years.
Dogs become infected through the ingestion of L₃ larvae of *S. lupi*. This occurs through the direct consumption of coprophagous beetles or the consumption of contaminated food; rodents, birds, rabbits and lizards as paratenic hosts are another potential transmission route. Larvae penetrate the stomach wall of dogs and migrate to the thoracic aorta via the gastric arteries. The larvae move to L₄ and immature adults. In 3-4 months they migrate to the esophagus where they mature and are surrounded by granulomatous nodules as part of the dog's inflammatory response (5,6).

During the necropsy of the dog three nodules were observed in the esophagus that during the mass allowed visualizing adult nematodes of *S. lupi*. In the histological study it was observed in the nodules with eosinophilic granuloma, with the presence of the nematode surrounded by a severe inflammatory infiltrate by neutrophils, eosinophils, lymphocytes, plasma cells and macrophages. These findings are in agreement with that reported by Diakou et al (25) who describe that the granulomas consist of a central area that are surrounded by degenerate and viable eosinophils, as well as the infiltration of neutrophils as part of the animal's immune response. Likewise, these are delimited by connective tissue infiltrated predominantly by mononuclear cells, specifically histiocytes, plasma cells and lymphocytes.

The pathogenesis of tumor induction by *S. lupi* has not been well elucidated (26,27). It is suggested that oesophageal sarcomas are produced by *S. lupi* larvae (3). It is believed that parasites interfere with cellular processes of relevance in carcinogenesis, acting in intercellular communication or through the secretion of molecules with carcinogenic potential (28). Fibrosarcomas and osteosarcoma can occur with the possibility of metastasis in the lungs (3), a pathology that did not occur in the case described in this study. The development of these tumors leads to oesophageal obstructions and dyspnea, which can lead to a severe clinical outcome that can lead to the death of dogs.

It is concluded that *S. lupi* is present in dogs from Yucatan, Mexico at low prevalence, producing lesions characterized by eosinophilic granulomas in the esophagus of dogs. The need to include this pathology in the differential diagnosis of esophageal and respiratory problems in dogs is revealed.
