1. Introduction

Necrotizing fasciitis (NF) is an aggressive infection of subcutaneous tissues that spread rapidly through the fascial planes. The incidence of NF is 0.40 cases per 100,000 people[1]. NF has a mortality rate of 34%[2]. The causes of necrotizing soft tissue infections in the lower extremities are animal or insect bites, blunt or penetrating traumas, ulcerated skin infections, drug injection, postoperative complications. Risk factors, such as being over 50 years old, diabetes mellitus, peripheral vascular disease, and other systemic diseases and poor nutrition, increase the mortality rate.

Colonial diverticulosis is a common disease prevalent among advanced age population. Diverticulitis can develop in 10%-25% of all patients with diverticulosis[3]. The main complications related to diverticulitis are abscess formation, free peritoneal perforation, intestinal obstruction, and internal fistulization.

The presentation of diverticular disease with extraperitoneal findings (<2%) and the development of NF as a complication (<1%) are rare[4].

In this article, we aimed to present a rare case of NF in the left thigh after retroperitoneal abscess fistulization due to diverticulum perforation without acute abdominal symptoms but the complaint of leg pain.

Rationale: Necrotizing fasciitis is an aggressive infection of subcutaneous tissues, which tends to spread rapidly through the fascial planes. Colonic diverticulosis is a common disease in advanced age, although it rarely causes a lethal necrotizing soft-tissue infection.

Patient concerns: A 58-year-old woman complained of left leg pain for 15 d without abdominal pain.

Diagnosis: Diverticulitis perforation presented as necrotizing fasciitis of the left thigh.

Interventions: Extensive debridement.

Outcomes: The patient died due to sepsis-induced multiple organ failure and severe metabolic acidosis.

Lessons: Clinicians should be aware of presentations of diverticulitis in patients who have a soft-tissue infection in lower extremity even though patients may not have had a history of diverticulosis or abdominal pain.
2. Case report

A 58-year-old female patient was admitted to the hospital with the complaint of left leg pain for 15 d. She had hypertension and underwent cervical cancer surgery seven years ago, therefore, she had a history of radiotherapy and chemotherapy.

During the physical examination, the patient was conscious, oriented, and cooperative. The results of the examination were as followings: Blood pressure 100/60 mmHg; heart rate 110 beats/min; respiratory rate 16/min; body temperature: 36.7 °C; SpO₂: 96%.

Abdomen examination did not reveal abdominal tenderness, defense or rebound. Laboratory test results on admission showed white blood cell (WBC) 12 000/µL (3 700/µL-10 000/µL), hemoglobin 7 g/dL (10.8 g/dL-14.2 g/dL), C reactive protein (CRP) 34 mg/dL (<0.5 mg/dL), creatinine 1.44 mg/dL (0.50 mg/dL-0.90 mg/dL), glucose 65 mg/dL (74 mg/dL-106 mg/dL), sodium 142 mEq/L (136 mEq/L-145 mEq/L), albumin: 2.2 g/dL (3.5 g/dL-5.2 g/dL), lactate: 1.2 mmol/L (0.5 mmol/L-2.0 mmol/L). X-ray of the left
thigh revealed extensive gas within the soft tissue (Figure 1).

LRINEC score were 6 points, as followings: CRP: 34 mg/dL (CRP>15 mg/dL; 4 points); WBC count: 12 (WBC<15; 0 point); Hemoglobin: 7 g/dL (Hgb<11 g/dL; 2 points); Sodium: 142 mmol/L (Na>135 mmol/L; 0 point); Creatinine: 1.44 mg/dL (Cr<1.6 mg/dL; 0 point); Glucose: 65 mg/dL (Glucose <180 mg/dL; 0 point).

Abdominal computed tomography showed a pouch filled with extra-lumination of the oral contrast agent extending to the retroperitoneum at the descending colon level.

Abdominal computed tomography scan showed a collection area extending from the paravertebral space to the left inguinal canal in the iliac fossa adjacent to the iliopsoas muscles with accumulation of gas (Figure 2).

The patient, who had a systemic inflammatory response and was thought to have sepsis due to perforation and NF, was treated with operation.

During operation, the perforated area of the sigmoid colon and the abscess in the retroperitoneum where fistulation towards the thigh was seen. Extensive debridement was performed after 22 h when the patient was referred to the emergency department. The patient was thought to have a polymicrobial infection and was given teicoplanin i.v., 2 g/dL, and meropenem i.v., 2 g/dL.

The patient was followed-up in the postoperative intensive care unit, and intermittent dressing and debridement were performed. Methicillin-sensitive and coagulase-negative Staphylococcus and Escherichia coli were isolated in abscess culture.

On the 9th day of postoperative follow-up, the patient died due to sepsis-induced multiple organ failure and severe metabolic acidosis.

3. Discussion

NF cases which develop in the thigh due to diverticulitis perforation are rare, and we found only 13 cases in the literature.

Kumar et al. reported that 94% of the cases presented with extremity pain[5]; while Angoules et al. reported that 73% of patients presented with erythema and 63% with pain[6]. In all of the 13 cases in our literature search, the complaint was limb pain as in our patient. Only 46% of these cases had erythema[7-12]. Otherwise, 8% of them had abdominal pain[8,12]. Therefore, patients with NF of the lower extremity due to diverticulitis perforation may present with only limb pain without abdominal pain or skin signs.

Twenty-three percent of the cases we found in the literature had a history of chronic steroid use due to rheumatoid arthritis[7,9,10]. Kumar et al. reported 10% of cases used chronic steroid, but Angoules et al. reported only 3% of patients had a history of steroids[5,6]. Although it was not presented in our case, it was seen that the history of chronic steroid use was more frequent in patients with NF due to intestinal perforation. This inference may indicate that steroid use may cause a potential delay in diagnosis by suppressing inflammation and may play a role in the development of NF in the lower extremity after intestinal perforation.

Same with our case, in 53% of the other 13 cases, air images were seen in the soft tissue through extremity X-rays[7-11,13,14]. The extremity X-rays is frequently used in trauma patients, and is quickly and easily accessible. X-rays may be ordered primarily in non-traumatic extremity pains and may direct the physician to the accurate diagnosis in the presence of a positive finding.

Clinicians should pay more attention to NF which has a high mortality rate in patients with leg pain and sepsis symptoms. Also, diverticulitis perforation should be kept in mind in the etiology of NF in the lower extremity, even if there is no abdominal pain or other common causes.

Conflict of interest statement

The authors report no conflict of interest.
